(Received 16 January 2001; accepted for publication 25 April 2001)

Ultrafast dynamics of free carriers in low-temperature grown GaAs was studied using time-domain terahertz emission spectroscopy. The subpicosecond free-carrier lifetime was determined for a set of annealed samples with different growth temperatures (175–250 °C), the carrier mobility was also estimated. The influence of the growth temperature on the ultrafast carrier trapping is discussed. © 2001 American Institute of Physics. [DOI: 10.1063/1.1380414]

I. INTRODUCTION

Low-temperature grown GaAs is the most widely used material for the fabrication of photoconductive THz emitters or detectors. Its unique properties are good carrier mobility, high dark resistivity, and subpicosecond carrier lifetimes.

GaAs grown by molecular beam epitaxy (MBE) at temperatures lower than 300 °C (LT GaAs) presents a 1%–2% arsenic excess which depends on the growth temperature \( T_g \) and on the arsenic pressure during the deposition.\(^1\)\(^2\) As a result a high density of arsenic antisite defects \( \text{As}\text{Ga}^\text{+} \) is produced and forms a donor miniband close to the center of the band gap.\(^3\)\(^4\) The concentration of \( \text{As}\text{Ga}^\text{+} \) increases with decreasing \( T_g \) and can reach \( 10^{19} \)–\( 10^{20} \text{ cm}^{-3} \), which leads to a decrease of the resistivity due to hopping conduction.\(^5\)\(^6\) The concentration of ionized donors \( \text{As}\text{Ga}^\text{+} \), which are responsible for the fast electron trapping, depends strongly on the concentration of acceptors (gallium vacancies).\(^7\) The as-grown samples are then usually thermally annealed: The excess arsenic precipitates into metallic clusters surrounded by depleted regions of As/GaAs barriers which allow one to recover the high resistivity.\(^9\) The role of the precipitates in the fast carrier recombination process is, however, not yet completely clear. Recently, attempts have been made also to dope LT GaAs during the MBE growth with compensating acceptors, namely with Be, in order to increase the number of \( \text{As}\text{Ga}^\text{+} \): the trapping time reduction was observed for heavily doped samples.\(^10\)\(^11\)

A detailed understanding of the mechanisms of the ultrafast response is a crucial point that allows one to optimize the elaboration technology and to control the properties of the material. As the photocarrier trapping is a nonradiative process in undoped LT GaAs samples, photoluminescence measurements cannot be used for the carrier lifetime determination.\(^3\)\(^1\)\(^1\) The most commonly applied technique is thus the optical pump–probe experiment.\(^3\)\(^1\)\(^2\)\(^1\)\(^2\)\(^1\)\(^3\)\(^1\)\(^4\) However, the interpretation of the obtained pump–probe signals is difficult as (i) several decay components are usually observed including the photocarrier trapping and cooling, and the photoinduced absorption,\(^1\)\(^8\) and as (ii) high excited-carrier densities (\( 10^{17} \)–\( 10^{19} \text{ cm}^{-3} \)) have to be used. Consequently, a large number of physical phenomena can contribute to the observed signal: band filling, carrier scattering, band-gap renormalization, free-carrier absorption, trapped-carrier reabsorption, filling of the miniband states. The observed effects thus depend significantly on the pump intensity and on the pump/probe wavelength. These problems can be avoided using the optical pump–terahertz (THz) probe experiments as discussed in Ref. 19; on the other hand, the temporal resolution in these experiments is decreased to about 400 fs due to the length of the THz pulses.

In this contribution we propose a method for extracting the subpicosecond photoexcited carrier dynamics directly from the temporal wave form of the THz pulses which are emitted from a biased LT GaAs sample. The advantage of this method is that the photo-induced absorption is avoided, that the measurement is not sensitive to the carrier cooling, and that low carrier densities (less than \( 10^{15} \text{ cm}^{-3} \)) are used: Thus the trap filling and the screening of the carriers can be completely neglected. Also, time constants as small as 250 fs can be detected.

II. EXPERIMENTAL METHOD AND RESULTS

The samples investigated in this study were grown by MBE on a semi-insulating GaAs substrate: First, a 72.5 nm GaAs buffer layer was deposited at 600 °C, subsequently, a 1.3 μm layer was grown at a temperature \( T_g \). Four samples were prepared with \( T_g = 175, 200, 225, \) and 250 °C. The samples were then annealed for 10 min at 600 °C. Gold planar electrodes were deposited on the layer surface with two different spacings (4 and 6 mm).

During the experiments a high bias voltage was applied on the electrodes (between 800 and 2500 V), the space between them was then uniformly irradiated by a femtosecond pulse train coming from a Ti:sapphire oscillator (λ = 800 nm, \( t_p = 100 \text{ fs} \), repetition rate 76 MHz): the generated free-electron densities ranged from \( 10^{14} \) to \( 10^{15} \text{ cm}^{-3} \). The
emitted THz signal was detected in the far field through electro-optic (EO) sampling using a 1-mm-thick (110) ZnTe crystal. The far-field profile of the THz pulse is proportional to the space derivative of the current between the electrodes. It is important to stress that no focusing optics should be used in the path of the THz beam in order to avoid wave form distortion due to the phase change and spectral filtering. In our approach the whole shape of the THz electric field is fitted in contrast with the emission experiments carried out in quantum wells and superlattices where only the resonant frequency was being determined, and that are thus less sensitive to the presence of mirrors and lenses.

The experiments were performed under nitrogen atmosphere in order to avoid water vapor absorption. We verified for all studied samples that, within the above-specified ranges, the shape of the THz wave forms depends neither on the distance between the electrodes, nor on the magnitude of the applied voltage, nor on the incident light intensity. Examples of the measured wave forms are given in Fig. 1. The shape of the wave forms is essentially given by the dynamics of the carriers in the LT GaAs layer and in the GaAs substrate (13% of the incident power is absorbed in the bulk) and by the detection process in the ZnTe sensor.

The relation between the true THz wave form and the wave form obtained through the EO sampling has already been described. The complex THz spectrum is simply multiplied by the autocorrelation of the optical pulse and by spectral characteristics of the EO crystal. We have experimentally determined the THz dielectric spectrum and the group refractive index near 800 nm for our ZnTe sensor. These data were then used for the fitting.

III. THEORETICAL MODEL AND DISCUSSION

The transient current density \( j \) through the emitter causes the emission of a THz field \( E_{\text{THz}} \). Far from the emitter, the on-axis field is given by

\[
E_{\text{THz}} \propto \int \frac{\partial j}{\partial t} \, dx \, dy \, dz,
\]

where the integration is taken over the whole emitter. The current density depends on the free-carrier concentration \( n \) and on the mean velocity \( v \) of the electrons:

\[
j = -env,
\]

the contribution of the holes which have a much smaller mobility is neglected. Our model of the carrier transport is based on a set of kinetic equations which can be written for the LT GaAs layer as well as for the GaAs substrate as follows:

\[
\frac{dn}{dt} = -n \tau_e + G(t, r),
\]

\[
\frac{dv}{dt} = -\frac{v}{\tau_v} + \frac{eE_{\text{loc}}(r)}{m^*} - \frac{vG(t, r)}{n},
\]

where \( G \) is a photoinjection rate, \( E_{\text{loc}} \) is the local electric field, \( \tau_e \) is the free-electron lifetime, and \( \tau_v \) is the velocity relaxation time. A term describing the carrier diffusion was omitted in Eq. (3) as it has no impact on the subpicosecond dynamics. The last term of Eq. (4) allows one to define correctly the mean velocity \( v \) of the free carriers during the generation process: \( dn = G \, dt \) is the density of the newly generated carriers with zero average speed, thus the change of the average speed of all the carriers is

\[
\frac{dv}{dt} = -v \frac{G(t, r)dt}{n}.
\]

This treatment is necessary as the velocity relaxation time in the substrate is longer than the excitation optical pulse.

If the emitter is irradiated at normal incidence, the photoinjection rate \( G \) can be factorized:

\[
G(t, r) = g(t)h(x, y)f(z),
\]

where the \( z \) axis is normal to the emitter surface. We used an excitation beam with a diameter exceeding the gap between the electrodes, consequently \( h(x, y) \) is only a very slowly varying function. As Eq. (3) is linear with constant coefficients, and since the initial carrier concentration is negligible, the free-carrier concentration can be factorized in a very similar form:

\[
n(t, r) = n(t)h(x, y)f(z).
\]

We assume that the variation of the local electric field \( E_{\text{loc}} \) along \( z \) is very slow near the surface where most of the carriers are generated. Using similar arguments as for the free-carrier concentration, the solution of Eq. (4) can be written in the form:

\[
v(t, r) = v(t)E_{\text{loc}}(x, y).
\]

It can be then shown that Eq. (1) becomes after the integration:
The excess arsenic incorporated in the material significantly lower than the number of traps. This condition is fulfilled in our experiment. The number of traps is order of magnitude as those reported in Refs. 19 and 29. For the samples grown at 225 and 250 °C the mobilities agree in the same crystals of GaAs. In contrast, for heavily damaged materials like LT GaAs elastic scattering by neutral and ionized impurities prevails. The mobilities of our samples are 2250–3000 cm² V⁻¹ s⁻¹. These values are in good agreement with theory of neutral impurity scattering in GaAs with a neutral impurity density of Nₐ = (4.1–5.4) × 10¹⁸ cm⁻³ [Ref. 31].

The velocity that the photocarriers acquire due to the applied bias field in our experiments does not exceed the thermal velocity. Therefore, the scattering cross section which follows the 1/ν⁴ law for elastic scattering is not influenced by the bias voltage. This again agrees with the observation that the temporal shape of the THz transient is independent of the applied bias voltage.

In our experiment the excitation wavelength is λ = 800 nm: The photoexcited carriers acquire an excess energy of 130 meV. In case of low photoexcitation densities the trapping times are also independent of the excitation wavelength as has been demonstrated recently. The free-electron lifetimes we obtained agree very well with the values reported in Ref. 19 for samples grown at slightly higher temperatures. The whole set of lifetimes can be fitted by an exponential function

\[ \tau_{LT} = \tau_0 \exp(T_g/T_0) \]  

with \( T_0 = 66 \, ^\circ\text{C} \), and \( \tau_0 \approx 20 \, \text{fs} \). We can write the free-electron lifetime as

\[ \tau_{LT} = 1/(N_V \sigma) = 1/\left( \pi N R^2 V_s \right), \]  

where \( N \) is the defect density, \( R \) is the average defect radius, \( \sigma \) is the capture cross section, \( s \) describes the ability of the defect to capture an electron, and \( V_s \) is the electron velocity which is in our case practically equal to the thermal velocity. Within the unified As cluster model the amount of the elemental arsenic is given by the sample growth temperature and remains constant during subsequent annealing. This can be expressed by

\[ N_g R_g^3 = N_A R_A^3, \]  

where the index \( g \) stands for an as-grown sample and \( A \) stands for an annealed sample. Putting together Eqs. (11) and (12), and assuming, as shown in Ref. 9, that:

\[ N_g = N_{g0} \exp(-T_g/T_{g0}), \]  

\[ N_A = N_{A0} \exp(-T_A/T_{A0}) \]
one obtains:

\[ \tau_c(T_g, T_A) = \tau_0 \exp\left(2T_g/(3T_{g_0})\right), \]

(14)

with

\[ \tau_0 = \frac{\exp(T_A/(3T_{A_0}))}{\pi R_{g_0}^2 v_s (N_{A_0} N_{g_0}^2)^{1/4}}. \]

(15)

Using values given in Ref. 9, the value of \( \tau_0 \) can be estimated: one finds \( \tau_0 \approx 25 \text{ fs} \) for \( s = 1 \) and \( R_g \approx 2.3 \text{ Å} \), which is very close to the result of our fit. On the other hand, our fit yields \( T_{g_0} = 44 ^\circ \text{C} \). This value is slightly larger than the value reported in Ref. 9 (\( T_{g_0} = 30 ^\circ \text{C} \)) which was obtained from measurements of as-grown samples (let us recall that our samples were annealed at 600 °C). From this difference, we conclude that the annealing slows down the dynamics of LT GaAs grown at lower temperatures stronger than the dynamics of samples grown at higher temperatures. This suggests, in turn, that the ability of electron capture is reduced for As clusters comparing to point defects.

**IV. CONCLUSION**

In conclusion, we demonstrated the method of extraction of the ultrashort carrier lifetime directly from the terahertz wave forms emitted by biased samples. We determined the electron lifetimes and mobilities for several annealed LT GaAs samples grown at different temperatures. A simple geometrical model was used to relate these results to the previously published ones.

**ACKNOWLEDGMENTS**

Fruitful discussions with T. Korn and support through LT GaAs MBE-growth by W. Hansen and C. Heyn are acknowledged. This work was supported by the Ministry of Education of the Czech Republic (Project No. LN00A032).
